TESTING AND EVALUATION OF EXISTING TECHNIQUES FOR IDENTIFYING UPTAKES AND MEASURING RETENTION OF URANIUM IN MILL WORKERS

Prepared by Monserco Limited, under contract to the Atomic Energy Control Board.

ABSTRACT

Preliminary tests and evaluations of existing bio-analytical techniques for identifying uptakes and measuring retention of uranium in mill workers were made at two uranium mills. Urinalysis tests were found to be more reliable indicators of uranium uptakes than personal air sampling. Static air samples were not found to be good indicators of personal uptakes. In vivo measurements of uranium in lung were successfully carried out in the presence of high and fluctuating background radiation. Interference from external contamination was common during end of shift measurements. A full scale study to evaluate model parameters for the uptake, retention and elimination of uranium should include, in addition to the above techniques, particle size determination of airborne uranium, solubility in simulated lung fluid, uranium analysis in faeces and bone and minute volume measurements for each subject.

RÉSUMÉ

On a fait des essais et des évaluations préliminaires de techniques bio-analytiques existantes pour identifier l'apport et mesurer la rétention d'uranium chez les travailleurs à deux usines de concentration d'uranium. Les analyses d'urines se sont révélées des indicateurs d'apport d'uranium plus fiables que les échantillonnages d'air individuels. Les échantillons statiques d'air ne se sont pas révélés de bons indicateurs d'apports individuels. On a effectué avec succès des mesures in vivo d'uranium dans les poumons en présence d'un fond de rayonnement fluctuant et de haute énergie. L'interférence causée par la contamination extérieure était fréquente lors de la prise des mesures à la fin des périodes de travail. Une étude de grande envergure pour évaluer des paramètres modèles de l'apport, de la rétention et de l'élimination de l'uranium devrait inclure, en plus des techniques déjà mentionnées, la détermination de la dimension des particules d'uranium en suspension dans l'air, leur solubilité dans un fluide pulmonaire simulé, l'analyse de l'uranium dans les fèces et les os, ainsi que des mesures de volume infime chez chaque sujet.

TABLE OF CONTENTS

1.0 INTRODUCTION

This report describes the testing and evaluation of existing techniques for identifying uptakes and measuring retention of uranium in mill workers. As part of the research and development efforts of the Atomic Energy Control Board (AECB), this study addresses the protection of workers from uranium uptakes which can exert both chemical toxic effects on the kidney and radiological exposures to various body organs such as lung, bones and kidneys. The objective of this study was to evaluate the feasibility of applying to uranium mill workers the existing bio-analytical techniques (first established for uranium fuel fabrication workers) for identifying uptakes and measuring retention of uranium in occupational environments. The measurement techniques tested and evaluated include bioassay determinations of uranium in urine and lung, measurements of uranium in air and measurements of Th234/U238 equilibrium.

On May 13, 1982 Monserco staff began preparing equipment, gathering supplies and organizing the program to be carried out at two uranium mills (operated by different companies) having different end products (a) ammonium diuranate and (b) a combination of ammonium and magnesium diuranate. At meetings arranged by the AECB on June 22, 1982 Monserco staff described the study to management and safety personnel of both companies and executives of the union representing the subjects. Six volunteers were selected from each of the two companies and the experimental program was explained to them in detail.

The testing program was begun on September 18, 1982 and continued uninterrupted through to October 22, 1982. Airborne uranium concentrations were measured by using

static air monitors and personal air monitors given to each subject. Urine specimens were collected from each subject and uranium concentrations were measured. Uranium lung burdens were measured using gamma spectroscopy. Some urine samples were split and aliquots sent for inter-laboratory comparison to the Radiation Protection Bureau (RPB) of Health and Welfare Canada. Calibration of the lung counting system had previously been carried out in May 1982 using the Rando phantom from the RPB.

The study was intended to test measurement techniques and not as an assessment of prevailing conditions in uranium mills. No attempt was made to select subjects as representative of mill conditions and therefore these results should not be used to draw conclusions about general conditions at either of the uranium mills involved. Neither should the mills be compared one to the other on the basis of the results reported below.

2.0 EXPERIMENTAL PROGRAM

The experimental program included a total of 12 subjects, 6 from each of the two facilities. The subjects were all above ground workers in the mill environment and were exposed to one or both of magnesium and ammonium diuranate. There was continuous coverage, while at work, of all 12 subjects throughout the five weeks of the study. Workers who used respirators or other protective breathing devices were excluded from the study so that there would be the highest probability of direct relationships between air, urine and lung measurements.

2.1 Uranium in Urine Determinations

The urinary system is one of the two routes for elimination of uranium after inhalation and was monitored closely in this study.

Urine samples were collected from all of the subjects on a regular basis and uranium in urine determinations were made by the delayed neutron counting technique. From some specimens duplicate samples were taken and sent to the Radiation Protection Bureau for analysis. In addition, some duplicates were analysed by Monserco.

Two sampling regimes were used during the five week collection period. One sampling regime covered a continuous 72 hour period during which each and every voiding was collected in a separate specimen bottle. The subjects recorded the date and time of voiding. Each specimen was analysed separately for uranium and the volume was measured. Throughout the remainder of the five week study period each subject was requested to give a urine sample immediately before starting a work shift and a separate specimen immediately after showering and changing clothes at the end of the work shift. For both specimens, the subjects were requested to empty the bladder completely and record the time of voiding and the time of the previous voiding. Each specimen was analysed separately for uranium and the specimen volume was measured.

2.2 Personal Air Sampling

Throughout the five weeks of the study each of the 12 subjects was issued a personal air sampler with a new filter for each work shift. The impactor filter heads were of CANMET design and at a flow rate of 1.9 litres per minute passed only respirable size particles with a mass distribution similar to a horizontal elutriator. The air pumps used were SIMQUADS manufactured by Cassella and controlled flow rate pumps from Dupont. Type A-E glass fibre filters were used to collect the respirable

size particles rather than silver membrane filters because of the lower background count rate for delayed neutron counting. The operating time of the SIMQUAD pumps was determined by means of the counter. Due to battery limitations the pump operating time was not necessarily equal to the length of the shift. Each of the glass fibre filters was individually analysed for uranium loading by the delayed neutron counting method.

2.3 Static Air Sampling

Throughout the 5 week study two static samplers were located at work sites at each of the two mills. Separate filters were installed for each work shift and the uranium on each filter was later determined by delayed neutron counting.

An automatic timer controlled the operation of the air pump and pumping rates were held constant at either 0.84 or 0.60 m^3/h through the use of critical orifices. The open face filter head was supported 1.7 metres above the floor and membrane filters with pore size 0.8 µm were held with the plane of the face perpendicular to the floor.

2.4 Th234/U238 Equilibrium Measurements

Samples of uranium product were collected from each of the mills and the Th234/U238 equilibrium was determined by gamma spectroscopy using phoswich detectors. The equilibrium condition of inhaled uranium has significance with respect to the lung counting technique described below because Th234 the first daughter of U238 is the radioisotope measured.

After chemical separation of thorium from the uranium product in the milling process the Th234/U238 equilibrium will also be disrupted. The extent of disequilibrium

in a given sample was determined by making a comparative measurement of the ratio of the 63-93 keV region (Th234) to the 185 keV region (U235) in the unknown sample. A similar measurement was made of a sample in which it was known that equilibrium had been established.

About 100 mg of each sample was spread into a thin layer between sheets of plastic which were glued together. Alternately, the 12.5 cm square samples were sandwiched between two 12.5 cm diameter phoswich detectors and the gamma spectra accumulated.

2.5 Uranium Solubility in Simulated Lung Fluid

Samples of the materials that had been collected for the analysis of Th234/U238 equilibrium were to be used for determination of solubility in simulated lung fluid.

2.6 Thorax Burden Measurements

Throughout the last four weeks of the study uranium lung burden determinations were made on each of the 12 subjects. Measurement times for each subject were split between the beginning and the end of the work shift. The Monserco Mobile Lung Counter was positioned close to both mills for the convenience of the subjects and to minimize lost work time. The location of the counter was also based in part on the results of a survey of background radiation in the vicinity of the two uranium mills.

The measurement procedure, which has been documented by Monserco (Ref. 4) required that the subject change into a set of clothes provided by Monserco and then lie supine

in a shielded bed. Two phoswich detectors were positioned 8 cm above the center of the lungs and a 33 minute measurement was made. Either before or after the measurement of the subject a background measurement was made using a water phantom. At least once each day gamma energy and efficiency measurements were checked.

3.0 RESULTS

3.1 Uranium in Urine Measurements

The results of the spot uranium in urine measurements made at the beginning and end of each work shift are given separately for each worker in Tables 1 to 23. The shift hours worked by the subject on each date are given in column 2 and the data pertinent to the urine sample given at the beginning of the shift are recorded in columns 6 to 9 on the same line. The data pertaining to the urine sample given at the end of the shift are recorded immediately below. The time of voiding and the time of the last previous voiding were recorded. The volume of urine in the specimen was measured and recorded before a 40 mL aliquot was taken for delayed neutron counting. The minimum detectable concentration of uranium was 2µg U/L of urine.

The results of the 72 hour continuous urine sampling program are given for each subject in Appendix 1. The first two digit entry under the Company Code column is the subject's number followed by the day and the month. The time that the sample was given and the volume are also recorded.

The results of the interlaboratory comparison measurements between Monserco and RPB are summarized in Table 28. In general there is good agreement between the two sets of analysis with a correlation coefficient of 0.87.

3.2 Personal Air Sampling

The results of the personal air sampling measurements which covered all work shifts throughout the study period are given separately for each subject in Tables 1 to 23. A new glass fibre filter was used for each subject for each shift. The operating time of the SIMQUAD pumps is recorded in column 4 in hours. Column 4 is left blank for the Dupont pumps. Each filter was analysed separately for uranium content by delayed neutron counting and the result is entered in column 5. Unused glass fibre filters were tested and found to contain 0.02 µg uranium on average whereas, silver membrane filters were found to contain uranium (or equivalent interference) ranging as high as 10 µg.

Reference Man (Ref. 2) doing light work inhales 20 L of air per minute. Since the personal air samplers operated at 1.9 L/min., the amount of uranium inhaled by the subject during the operating time of the pump is about 10 times the amount of uranium on the filter.

3.3 Static Air Sampling

Static air samplers in Facility A were located in the drum filter areas (air sampling pumps 111 and 112). The results of the measurements are recorded in Tables 29 and 30. The air concentration reported in the right hand column includes airborne particles of all sizes. All six subjects from Facility A were on the same shift so the timer controls on the static air pumps were set to operate during these shifts.

3.4 Th234/U238 Equilibrium Measurements

Various samples of process material were collected during the 5 week study period and analysed for Th234/U238 equilibrium ratio. Such potential airborne material as precipitation tank overflow and drying and packing product were gathered. The results of some of these analyses showed a surprisingly high fraction of Th234 present at the time that the samples were taken. All five samples of 'yellowcake' in which there were very high concentrations of uranium had Th234 at 60 to 72% of equilibrium with U238. All of the drum sludge materials that were sampled were so high in Th232 and its daughter radiations that Th234 and U235 were undetectable.

3.5 Uranium Solubility Measurements

The results of uranium compound solubility in simulated lung fluid were not available at the time of printing of this report.

3.6 Thorax Burden Measurements

Using a scaling dosimeter, a gamma survey had been made of possible Mobile Lung Counter sites near the uranium mills. The results of that survey are recorded in Table 25 and indicated background radiation levels about three times the level measured at Monserco's Lab in Mississauga. Since all usable locations had equivalent background levels, the counter was located at a camp site near the mills for the convenience of the subjects.

The results of initial background and control person measurements indicated that the scattered radiation from a water phantom inside the shielded bed was only twice as high as it had been at Mississauga and the total

radiation from a control person was only 50% higher than at Mississauga. This is a consequence of the fact that when a control person is measured at Mississauga 50% of t e observed radiation from the subject originates within the subject (K40, Cs137 etc.) and the other 50% is scattered radiation from outside the shield.

Throughout the five week study period there were significant temporal fluctuations in the background measured within the shielded bed. This background is partially caused by the decay of radon daughters and the fluctuations appeared correlated with changes in atmospheric conditions around the shield. The analytical background subtraction model, described in procedure M21 Rev. 1, adequately compensated for the variations in background. However, the increased average background level resulted in an increase in the minimum detectable amount (MDA) of uranium in the lung from 4 mg to 6 mg.

Three to five lung burden measurements were made on each of the subjects throughout the last four weeks of the study period and a single measurement was made on each of 17 control people. To determine the background subtraction when calculating lung burdens the following model was used.

$$B1 = (C1 + C2 \times C) \times B2$$

where B1 = counts in the 38 to 110 keV region of the spectrum.

C = chest circumference in metres

B2 = counts in the 110 to 165 keV region of the spectrum

C1, C2 constants to be evaluated.

The values for C1 and C2 were calculated to be 1.48 and 0.59 from a least squares fit of the control group and subject data to the above function. The lung burdens were then evaluated by calculating a value for B1 based on the observed value of B2, subtracting the calculated value of B1 from the observed value of B1 and multiplying by the normalizing and calibration factors determined using the RPB Rando phantom: 86.9 counts per 2000 seconds per mg uranium. The results are recorded in column 10 of Tables 1 to 23 in the row corresponding to the date on which the measurement was made. The notation 'B' or 'E' was used to denote measurements made Before the subject started his work shift and at the End of the work shift respectively.

4.0 DISCUSSION

For each subject, personal air sampling data was used to calculate the amount of uranium inhaled during each work shift. In order to make this calculation it was assumed that the airborne uranium concentration was the same for the full 8 or 12 hour shift as was measured during the operating time of the pump. Also it was assumed that the breathing rate of the subject was 20 L/min as recommended by ICRP for Reference Man doing light work (2). The calculated values for the uranium inhaled during each shift throughout the study period were averaged, and the standard deviation calculated. The results are shown in Table 34. Also shown are the averages and standard deviations of the end of shift uranium in urine concentrations. There is an apparent correlation between these two variables which merits further investigation because, if verified, it indicates that working limits could be established on the basis of urinalysis alone. On a subject by subject basis the

results of individual personal air samples and end of shift urine samples that exceeded one standard deviation above the respective average values are identified, recorded in Table 35, and classified in Figure 1. Those entries which appear in the upper right box indicate agreement. Entries in the upper left and lower right segments indicate either a false positive or a false negative result for one procedure. On two occasions air sampling was identified as giving a false positive result because the sampler operated only a small fraction of the total shift time and therefore, did not collect a representative sample of the shift average air concentration. Out of a total of 22 'events' only 5 resulted in agreement. On 9 occasions there was either false positive urinalysis or false negative personal air readings. For the remaining 6 occasions there were either false positive indications for air sampling or false negative urinalysis. Again, if confirmed, these data would indicate that if only one monitoring technique were to be used it should be urinalysis since there would be fewer false negative events and consequently fewer undetected uptakes. This result is not surprising since personal air monitoring has several limitations by comparison with urinalysis. Air monitors operate at flow rates which may not represent accurately individual inhalation rates since respiration depends on many factors such as the difficulty of the task. In addition, personal samplers cannot reflect precisely the concentration of inhaled air although attempts are made to position the sampling head in the breathing zone. Finally, in the work environment of uranium mills it would be impossible for existing personal air samplers to provide complete coverage. With appropriate sampling procedures, if one urine sample is missed or rendered useless, another can be taken with little information loss. If a personal air sampler fails to operate and such

a condition is undetected there is no means of regaining the lost information. In future studies the accuracy of the calculation of inhaled uranium could be significantly improved by making measurements of minute volumes for each subject doing light work. This would provide subject specific data to be used in place of the default value of 20 L/min. recommended by ICRP.

The limitations imposed by the numbers of subjects studied mean that it is unlikely that correlations between static air sampling data and individual subject uptakes would be significant. The present data indicate that there is little agreement between these measurements. There was one occasion (Oct. 20, subject 22) when both the personal air sampler and urinalysis indicated an uptake and the static sampler operating during that shift also indicated a high level. However, when the calculated amounts of uranium inhaled during the excursion are compared, the static sampler measurements give no indication of the true size of the uptake by the worker. The static samplers may be a suitable means of assessing the general air environment in specific areas of the mills but appear not to be effective for monitoring and protecting workers. It may be that the use of size selection heads on the static samplers will give more useful information about respirable uranium. A conclusive study must be organized with a larger number of subjects included for each task category so that these conclusions can be verified. Obviously from the workers viewpoint, static air sampling is the most convenient monitoring procedure.

The lung burden determinations have been calculated assuming that the equilibrium rate of Th234/U238 was unity. Since measurements showed that it was in the range 0.6 to 0.7, current lung burden readings are consistent with personal air sampling measurements that indicate maximum intakes

of 1.2 mg during the 5 week study (Subject 22, Oct 22). If there had been significant intakes in the past which resulted in chronic lung burdens, they would have been detected by the technique used since the equilibrium rates would have reached unity. Future measurements of equilibrium ratios will be determined using a HpGe detector to avoid interferences associated with Th232.

Based on personal air sampling, urinalysis and lung counting results, it appears that with the exception of subject 24 all the indicated lung burdens above 6 mg have been caused by some form of contamination. The 18keV x-ray from uranium was not prominent in the recorded spectra. This indicates that perhaps hair, nose or hand contamination rather than chest surface contamination may be present. If it is necessary to make measurements at the end of shifts different shielding configurations may be advisable to shield the hands or head.

Urinalysis results in this study suggest that the inhaled uranium is very soluble since it is cleared from the body quickly. If this is verified by uranium compound solubility in simulated lung fluid measurements, it may be necessary in future to measure uranium retention in bone to successfully determine mass balance relationships.

5.0 CONCLUSIONS AND RECOMMENDATIONS

It is necessary to identify and control airborne uranium uptakes by workers in order to prevent uranium from exerting both chemical toxic effects on the kidney and radiological exposures to various body organs such as lung, bones and kidneys.

Tentative conclusions concerning the usefulness of the monitoring techniques examined in this study were drawn by comparing the results of different procedures for the same subject. The conclusions reached must be tentative since the number of subjects examined was small. The primary goal of this study was to establish that these monitoring techniques could be applied to mill workers. The results indicate a large survey is a practical, worthwhile proposition which is likely to produce valuable information with respect to the optimum techniques required for personnel monitoring in uranium mills. The results of a complete full scale survey can be used to determine the appropriate monitoring procedures for personnel involved in specific job categories and to determine coefficients in applicable intake, retention and elimination models.

The data collected during this feasibility study indicate that personal air sampling, lung counting and urinalysis each, at least qualitatively, reflect uptakes, retention and elimination respectively of uranium in mill workers. Without detailed quantitative analysis in a larger group of subjects, it is not possible to determine whether any monitoring technique is sufficient on its own to describe uranium

metabolism. In order to make quantitative analyses of the parameters describing the uptake of uranium in mill-workers it will be necessary to take personal air samples of the breathing zone air around the subject. The determination of retention should include uranium in bone determinations as well as uranium in lung measurements. The minimum detectable amount for the latter will have to be reduced from current levels (6 mg) by decreasing background, relocating the mobile lab and extending counting times. Uranium elimination should be monitored from measurements of faeces and urine uranium content in order to determine mass balances. If the uptake, retention and elimination parameters can be established for the uranium compounds to which mill workers in various job categories are exposed, routine monitoring techniques will not need to include all of these procedures.

Our tentative analysis indicates that urinalysis appears to be the most reliable method of identifying uptakes of uranium. Urinalysis has the advantages of minimal interference with worker performance and a greater reliability and hence cost effectiveness. When the parameters relating retention and elimination are determined it will be possible to recommend testing frequencies, action levels and MDA levels. Depending on the outcome of the large scale study to follow and the results of solubility studies, it may be necessary to monitor routinely the lungs or bones of workers. There may be sufficient uptake of W and Y class uranium compounds that long term buildup of these materials may be of significance. Similarly the chronic intake of D class material may result in a long term buildup of uranium in bone.

A large scale follow-up study is required to address the points raised above. Quantitative determinations of the uptake, retention and elimination parameters for the various uranium compounds found in uranium mills is required. Optimum methods and monitoring schedules can then be established for all job types including maintenance, outside contractors and operations personnel. The proposed study must include statistically representative numbers of workers within each job and work history category for both males and females. The monitoring methods should include those used in this study together with minute volumes measurements, particle size determinations, fecal analysis and uranium in bone determinations. The fact that Monserco has successfully completed this pilot study indicates that the large scale study can be undertaken with confidence and that reliable conclusions can be reached upon which monitoring requirements for all workers in uranium mills can be established.

ACKNOWLEDGEMENT

The funds for this study were provided by Atomic Energy Control Board. The successful completion of the project was only possible as a result of the cooperation of many individuals and companies.

The twelve subjects who participated in the project were most cooperative and willing to carry out the extra tasks that were requested of them. The mine/milling companies gave support by making time available for the testing of their employees, providing some of the air sampling equipment and offering the assistance of their support staff. The assistance of the CANMET Laboratory in Elliot Lake which provided some personal air sampling pumps, and related equipment is also appreciated.

The Radiation Protection Bureau of Health and Welfare Canada which analysed some of the urine samples as part of an interlaboratory comparison program was most helpful.

URANIUM ANALYSIS IN URINE
SERVICE REPORT

REFERENCE: U-350

COMPANY NAME: PROJECT 271
AECB MILL STUDY

REPORT DATE: OCT. 5/82

SAMPLES RECEIVED: SEPT 28/82 50 SPECIMENS

RESULTS TELEPHONED: NO

ANALYSIS PROCEDURE: M12 REV 0
