**Abstract**

Preliminary calculations for ITER EDA ID have been performed using the 1/2D thermal equilibrium code HELIOS. It is found that:

- The maximum ignition margin for ITER ID (29%) is 6% less than for ITER OD (35%) and 5% less than for ITER CDA (34%).
- Decreasing the ratio  $\tau_{He}^*/\tau_E$  from the nominal value 10 to a value of 5 gives a 12% gain in the maximum ignition margin. Increasing the ratio from 10 to 15 causes a 22% loss in the margin. Furthermore, ignited equilibria no longer exist for  $\tau_{He}^*/\tau_E \geq 17.6$ .
- Operation in driven mode with 50 MW of external power increases the confinement capability by 13%. With 100 MW, the improvement is 24%.
- Lowering the fusion power from 1500 to 1000 MW slightly improves the maximum ignition margin (+5%) and allows operation below the Greenwald density limit.
- A 10% reduction of the toroidal magnetic field with a correlative diminution of the plasma current for constant safety factor operation, causes a dramatic reduction (-18%) of the maximum ignition margin.
- A fraction of neon of 0.68% would completely suppress the ignition margin. Furthermore, ignited equilibria, with the nominal fusion power and  $\tau_{He}^*/\tau_E$ , no longer exist when the neon fraction exceeds 0.75%.

## 1 Introduction

Results of 1/2D calculations performed with the HELIOS code [1] are presented using the following approximations and assumptions:

- No plasma volume correction due to the lower X-point,
- No synchrotron radiation,
- The confinement time for operation in H-mode with grassy ELMs is taken to be

$$\tau_{E, \text{scaling}} = 0.85 \times \tau_{E, \text{ITERH-93P-ELMfree}}$$

with [2]

$$\tau_{E, \text{ITERH-93P-ELMfree}} = 3.6 \times 10^{-7.57} \frac{M_{eff}^{0.41} \kappa_X^{0.66} I_p^{1.06} (\bar{n})^{0.17} B_t^{0.32} R^{1.9} a^{-0.11}}{P_{net}^{0.67}} \quad (\text{MKSA})$$

where the effective atomic mass  $M_{eff}$  is taken to be  $M_{eff}=2.5$  and  $P_{net}$  is defined as

$$P_{net} = P_\alpha + P_{OH} + P_{ext} - P_{rad}$$

where  $P_\alpha$ ,  $P_{OH}$ ,  $P_{ext}$ , and  $P_{rad}$  are the alpha power coupled to the plasma, the ohmic power, the external power, and the radiation losses (bremsstrahlung), respectively.

## 2 ITER parameters and model assumptions

The following parameters are taken for ITER CDA, ITER OD and ITER ID:

- ITER CDA

$$R = 6.00 \text{ m}, \quad a = 2.15 \text{ m}, \quad I_p = 22 \text{ MA},$$

$$B_t(R) = 4.85 \text{ T} \quad \text{giving} \quad q_{\psi=95} \simeq 3.01,$$

$$\kappa_{95} = 1.98, \quad \kappa_X = 2.22, \quad \delta_{95} = 0.39, \quad \delta_X = 0.58$$

$$P_{fus} = 1100 \text{ MW}$$

The volume correction due to the symmetrical X-points is taken into account.

- ITER OD

$$R = 8.11 \text{ m}, \quad a = 3 \text{ m}, \quad I_p = 24 \text{ MA},$$

$$B_t(R) = 5.72 \text{ T} \quad \text{giving} \quad q_{\psi=95} \simeq 3.02,$$

$$\kappa_{95} = 1.55, \quad \kappa_X = 1.60, \quad \delta_{95} = \delta_X = 0.25$$

$$P_{fus} = 1500 \text{ MW}$$

- ITER ID

$$R = 8.14 \text{ m}, \quad a = 2.80 \text{ m}, \quad I_p = 21 \text{ MA},$$

$$B_t(R) = 5.68 \text{ T} \quad \text{giving} \quad q_{\psi=95} \simeq 3.02,$$

$$\kappa_{95} = 1.60, \quad \kappa_X = 1.75, \quad \delta_{95} = \delta_X = 0.24$$

$$P_{fus} = 1500 \text{ MW}$$

The volume correction due to the lower X-point is not taken into account.

Following the recommendations of the JCT and Home Team members, we take

$$f_{Be} = \frac{n_{Be}}{n} = 2\%$$

where  $n_{Be}$  is the beryllium density and  $n$  the electron density.  $f_{Be}$  will be denoted the beryllium fraction.

Following the same recommendations, we take

$$n(\rho) = n_0(1 - \rho^2)^{\alpha_n} \quad \text{with} \quad \alpha_n = 0.15 \quad (1)$$

The recommended temperature profile is:

$$T(\rho) = T_0(1 - \rho^4)^3 \quad (2)$$

The corresponding peaking factor is

$$\frac{T_0}{\langle T \rangle} = \frac{35}{16} = 2.1875$$

The present version of the HELIOS code only accepts temperature profiles of the form:

$$T(\rho) = T_0(1 - \rho^2)^{\alpha_T} \quad (3)$$

The value of  $\alpha_T$  giving the same temperature peaking factor is:

$$\alpha_T = \frac{19}{16} = 1.1875$$

The above values for  $\alpha_n$  and  $\alpha_T$  will be taken for all the following calculations.

We have represented in Fig. 1 the density profile given by Eq. (1) (dashed line) and the temperature profiles given by Eq. (2) (solid line) and Eq. (3) (dash-dot line). All the profiles are normalized to the volume averaged values.

### 3 POPCON plot for constant $P_{fus}$ , $P_{ext}$ and $\tau_{He}^*/\tau_E$

We consider a tokamak with given density and temperature profiles and a given beryllium fraction.

Choosing a value of the temperature  $\langle T \rangle_n$  (density averaged temperature) and of the helium fraction  $f_{He}$ , we can calculate the density  $\langle n \rangle$  corresponding to a given total fusion power  $P_{fus}$ , from the following equation

$$P_{fus}(\langle n \rangle, \langle T \rangle_n) = C_\alpha \frac{\langle n \rangle^2}{4} \overline{\sigma v}_{DT}(\langle T \rangle_n) (E_\alpha + E_n) V$$

where  $\overline{\sigma v}_{DT}(\langle T \rangle_n)$  is the profile averaged thermonuclear reaction rate and where the dilution coefficient  $C_\alpha$  takes account of  $He$  and  $Be$  fractions [1].

- The helium particle content  $N_{He}$  and the helium source  $S_{He}$  may now be deduced, giving the apparent helium confinement time

$$\tau_{He}^* = \frac{N_{He}}{S_{He}}$$

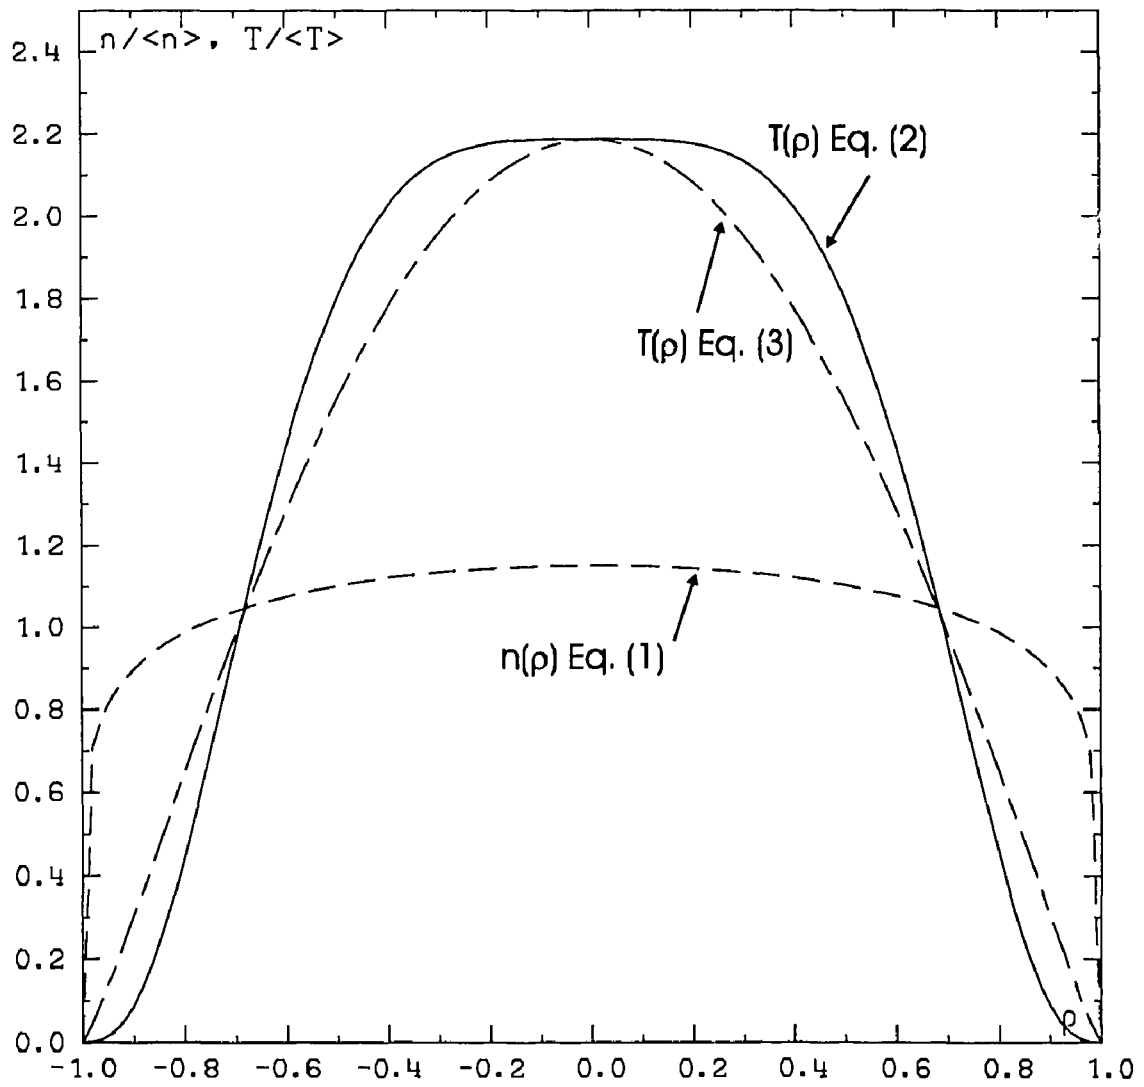

Figure 1: Density and temperature profiles.

- The alpha, ohmic sources and radiation losses may be computed as well as the thermal energy content. For a given external power  $P_{ext}$ , the thermal equilibrium equation

$$P_\alpha + P_{OH} + P_{ext} = P_{rad} + \frac{W_{th}}{\tau_E}$$

yields the required energy confinement time  $\tau_E$ .

Imposing a constraint on  $\tau_{He}^*/\tau_E$  gives an equation for  $f_{He}$  which has two or zero solutions. The corresponding curve in the  $(\langle n \rangle, \langle T \rangle_n)$  plane is a closed curve.

For each point lying on the above curve, the confinement time given by the scaling law may be computed, leading to the confinement capability  $M$  defined as

$$M = \frac{\tau_{E,scaling}}{\tau_E}$$

where  $\tau_E$  is the **required** energy confinement time given by the thermal equilibrium equation.

The confinement margin  $\Delta M$  is defined as  $\Delta M = M - 1$ . It will always be expressed in percent.

## 4 Comparison between ITER CDA, ITER OD and ITER ID

### 4.1 ITER ID versus ITER OD

Choosing  $P_{fus}=1500$  MW,  $\tau_{He}^*/\tau_E=10$ , the POPCON plot for ignition ( $P_{ext}=0$ ) is represented in Fig. 2 for ITER OD (dashed line) and ITER ID (solid line). The confinement capabilities are also given. The upper part of the closed curve corresponds to values of the confinement capability which are in general below 1. The corresponding value of  $\beta_N$  (the normalized toroidal beta) is above the Troyon limit. For the above two reasons, this part of the curve is plotted with a dashed line and will not be discussed below. We see that the confinement capability is maximum for a point called marginally sustained ignition (MSI) because it is the last surviving operating point when the confinement time is decreased with respect to the value given by the scaling law. MSI is obtained for  $\langle T \rangle_n \simeq 7.8$  keV in both machines. We see that the ignition margin is approximately 6% lower in ITER ID than it was in ITER OD.

### 4.2 ITER ID versus ITER CDA

The comparison between ITER ID and ITER CDA is shown in Fig. 3. MSI ignition is also obtained for  $\langle T \rangle_n \simeq 7.8$  keV in ITER CDA. We see that the maximum ignition margin is 5% less in ITER ID than it was in ITER CDA. However, extrapolation in the elongation dependance of the confinement time is made for ITER CDA up to values which are outside the database.

## 5 Effect of $\tau_{He}^*/\tau_E$ for ignition in ITER ID

The ignition curves for  $P_{fus}=1500$  MW are plotted in Fig. 4 for  $\tau_{He}^*/\tau_E=5, 10, 12, 15, 17.5$ . We see that increasing the apparent helium confinement time both reduces the operating range and increases the available operating densities. For  $\tau_{He}^*/\tau_E \geq 17.6$ , the ignition curve no longer exists.

Values of the confinement capabilities are given in Fig. 5 for  $\tau_{He}^*/\tau_E=5, 10, 15$ . The ignition margin at MSI gains 12 % when  $\tau_{He}^*/\tau_E$  decreases from 10 to 5; it losses 22 % when  $\tau_{He}^*/\tau_E$  increases from 10 to 15.

## 6 Operation in driven mode

Constant  $P_{fus}, P_{ext}$  curves are plotted in Fig. 6 for  $P_{ext}=0, 50, 100$  MW. We see that operation in driven mode with increasing external power both widens the operation temperature range and allows operation at lower densities.

Constant  $P_{fus}$  curve with  $\tau_a^*/\tau_E=10$

 Scaling  $0.85 * ITERH93PELM_{free}$   
 $T_i=T_e$ , no synchrotron

Figure 2: Comparison of ignition margins in ITER OD and ITER ID,  $P_{fus}=1500$  MW,  $\tau_{He}^*/\tau_E=10$ . The numbers which label the operating points are the confinement capabilities  $M$ .

Constant  $P_{fus}$  curve with  $\tau_{He}^*/\tau_E=10$

ITER CDA (dot):  $P_{fus}=1100$  MW and EDA ID:  $P_{fus}=1500$  MW  
 Ignition, Scaling  $0.85 \times \text{ITERH-93P-ELM-free}$   
 $T_i=T_e$ , no synchrotron

Figure 3: Comparison of ignition margins in ITER CDA ( $P_{fus}=1100$  MW) and ITER ID ( $P_{fus}=1500$  MW) for  $\tau_{He}^*/\tau_E=10$ .

Constant  $P_{fus}$  curve with  $\tau_{He}^*/\tau_E=5, 10, 12, 15, 15.7$   
 ITER EDA ID,  $P_{fus}=1500$  MW, Ignition  
 $T_i=T_e$ , no synchrotron

Figure 4: ITER ID ignition curves for  $P_{fus}=1500$  MW and  $\tau_{He}^*/\tau_E=5, 10, 12, 15, 17.5$ .

Constant  $P_{fus}$  curve with  $\tau_{He}^*/\tau_E=5, 10, 15$

ITER EDA ID,  $P_{fus}=1500$  MW, Ignition  
 Scaling  $0.85 * ITERH93PELMfree$   
 $T_i=T_e$ , no synchrotron

Figure 5: ITER ID ignition curves for  $P_{fus}=1500$  MW and  $\tau_{He}^*/\tau_E=5, 10, 15$ .

Constant  $P_{fus}$  curve with  $\tau_{He}^*/\tau_E=10$   
 ITER EDA ID,  $P_{fus}=1500$  MW,  $P_{ext}=0, 50, 100$  MW  
 $T_i=T_e$ , no synchrotron

Figure 6: ITER ID constant  $P_{ext}$  curves for  $P_{fus}=1500$  MW,  $\tau_{He}^*/\tau_E=10$  and  $P_{ext}=0, 50, 100$  MW.

Values of the confinement capabilities are given in Fig. 7 for  $\tau_{He}^*/\tau_E=10$  and  $P_{ext}=50, 100$  MW. Marginally sustained thermal equilibrium (MSE) is obtained for  $\langle T \rangle_n \simeq 7.5$  keV in both cases. For  $P_{ext}=50$  MW, the confinement margin at MSE is 42 % (+ 13 % with respect to the pure ignition case). For  $P_{ext}=100$  MW, the confinement margin at MSE is 53 % (+ 24 % with respect to the pure ignition case).

Constant  $P_{fus}$  curve with  $\tau_{He}^*/\tau_E=10$

ITER EDA ID,  $P_{fus}=1500$  MW,  $P_{ext}=50, 100$  MW

Scaling  $0.85 * ITERH93PELMfree$

$T_i=T_e$ , no synchrotron

Figure 7: ITER ID constant  $P_{ext}$  curves for  $P_{fus}=1500$  MW,  $\tau_{He}^*/\tau_E=10$ , and  $P_{ext}=50, 100$  MW.

## 7 Effect of the fusion power

The ITER ID ignition curves are plotted in Fig. 8 for  $\tau_{He}^*/\tau_E=10$  and  $P_{fus}=1500$  MW (corresponding to  $\Gamma_n \simeq 0.96$  MW/m<sup>2</sup>) and 1000 MW ( $\Gamma_n \simeq 0.64$  MW/m<sup>2</sup>). Values of the confinement capabilities  $M$  are also given. We see that the ignition margin at MSI is slightly better at lower fusion power and that a range of operating points below the Greenwald density limit is now available.

Constant  $P_{\text{fus}}$  curve with  $\tau_{He}^*/\tau_E=10$

ITER EDA ID,  $P_{\text{fus}}=1500 \text{ MW}$ ,  $1000 \text{ MW}$ , ignition

Scaling  $0.85 * \text{ITERH93PELMfree}$

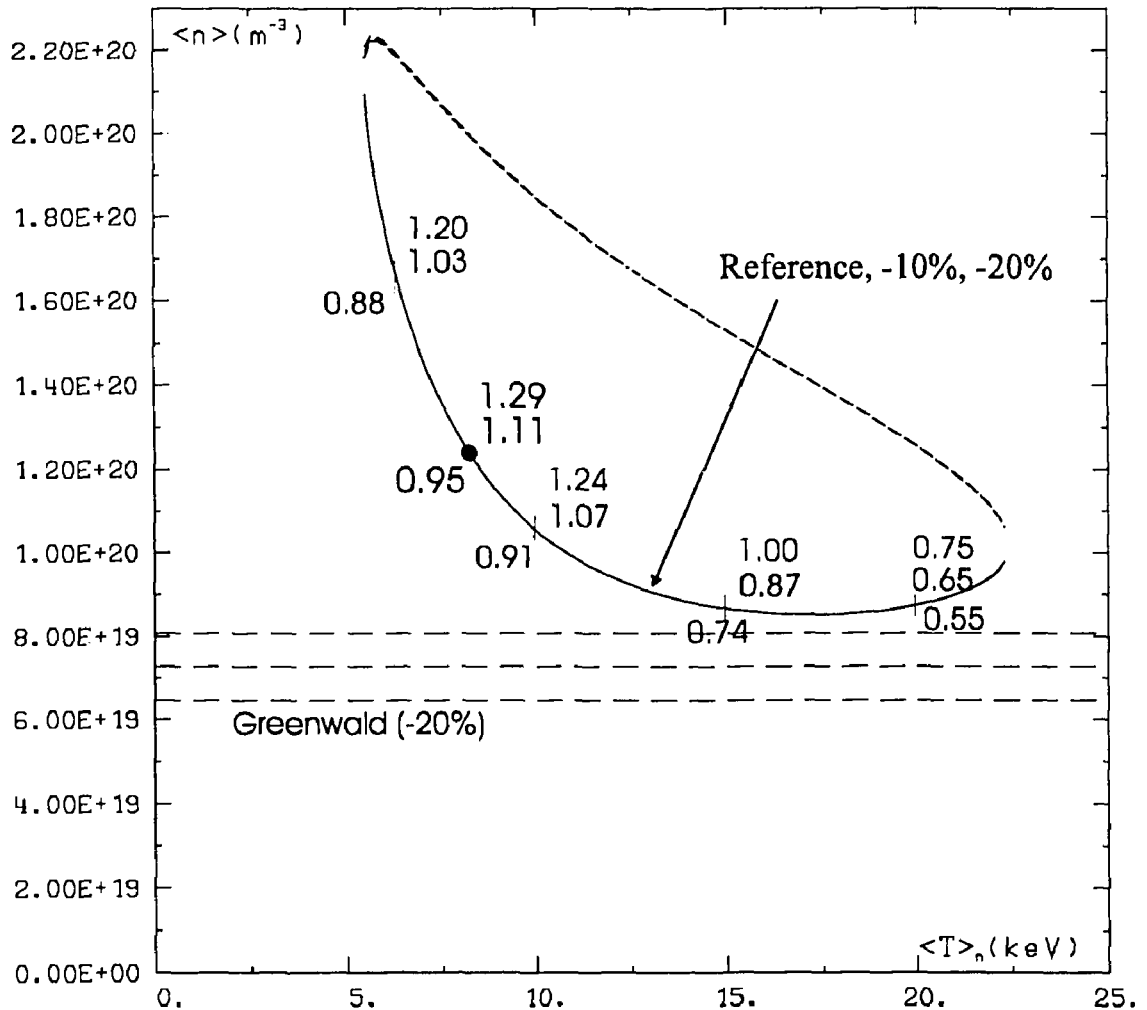

$T_i=T_e$ , no synchrotron

Figure 8: ITER ID ignition curves for  $\tau_{He}^*/\tau_E=10$  and  $P_{\text{fus}}=1500 \text{ MW}$  and  $1000 \text{ MW}$ .

### 8 Effect of the toroidal magnetic field intensity

The risk not being able to obtain the reference toroidal magnetic field must be taken into account. Here, we look at the consequence on the ignition margin of a reduction of the magnetic field intensity.

In Fig. 9, we have plotted the ignition curves corresponding to the reference magnetic field and to 10% and 20% reductions in both the magnetic field and the plasma current (in order to work at constant  $q_{9.95}$ ). We see that the  $(n, T)$  plots are practically identical for the three cases. The slight shift between the curves is due to the variation of the ohmic power. For a 10% reduction, the maximum ignition margin reduces to 11% (-18% relatively to the nominal value). For a 20% reduction, the ignition margin becomes negative (-5%) representing a 34% loss with respect to the nominal case.

Constant  $P_{fus}$  curve with  $\tau_{H_0}^*/\tau_E=10$

ITER EDA ID,  $P_{fus}=1500$  MW, 1500 MW, ignition  
 Reference and 10%, 20% reduction in  $B_t$  and  $I_p$   
 Scaling  $0.85 * ITERH93PELMfree$   
 $T_i=T_e$ , no synchrotron

Figure 9: ITER ID ignition curves for  $\tau_{H_0}^*/\tau_E=10$ ,  $P_{fus}=1500$  MW, for the reference  $B_t$ ,  $I_p$  and for a 10% and 20% reduction of these parameters.

### 9 Effect of the neon contents

Neon is envisaged in ITER as a seed impurity to obtain detached radiative divertor H-mode plasmas. In Fig. 10, we have represented the  $P_{fus}=1500$  MW,  $\tau_{H_0}^*/\tau_E=10$  ignition curves with fraction of neon in the main plasma  $f_{Ne}=0\%$ ,  $0.68\%$  and  $0.75\%$ . We see that the ignition margin is reduce to zero when  $f_{Ne}=0.68\%$ . For  $f_{Ne}=0.76\%$ , the ignition curve no longer exists.

Constant  $P_{fus}$  curve with  $\tau_{H_0}^*/\tau_E=10$   
 ITER EDA ID,  $P_{fus}=1500$  MW, ignition  
 $f_{Ne}=0\%$ ,  $0.68\%$ ,  $0.75\%$   
 Scaling  $0.85 \cdot \text{ITERH-93P-ELM-free}$   
 $T_i=T_e$ , no synchrotron

Figure 10): Effect of neon contamination on the ignition curves and ignition margins.

### 10 Conclusions

The above calculations have been performed without taking the small volume variation due to the lower X-point into account. The calculated ignition margins are then slightly overestimated. Inclusion of the correct geometry is in progress.

The calculations underline the great sensitivity of the ignition margin with respect to the helium content (dilution effect). However, we have found that ignition is still possible for  $\tau_{H^+}^*/\tau_E$  values as high as 15 provided averaged densities of about  $1.3 \times 10^{20} \text{m}^{-3}$  can be achieved.

Operation in driven mode with  $Q=30$  ( $P_{ext}=50$  MW) or  $Q=15$  ( $P_{ext}=100$  MW) considerably increases the confinement capability if proper operation of the divertor may be achieved.

Downgrading the fusion power output could allow operation at densities below the Greenwald limit at the expense of a reduction of the neutron flux.

Realizing the nominal magnetic field is essential. Lowering the field both considerably reduces the ignition margin and causes a downward shift of the Greenwald density limit with respect to the available operating densities.

Finally, we have seen that main plasma contamination by neon would prevent ignition for neon fractions as low as 0.7%.
