FEVRIER 2009
Abstract:

This research aims at clearing up misunderstandings about the distributive impacts of carbon taxes, which proved to be a decisive obstacle to their further consideration in public debates. It highlights the gap between partial equilibrium analyses, which are close to the agents’ perception of the costs of taxation, and general equilibrium analyses, which better capture its ultimate consequences. It shows that the real impact on households’ income inequality is not mechanically determined by the initial energy budgets and their flexibilities but also depends upon the way tax revenues are recycled and its general equilibrium consequences. The comparison of five tax-recycling schemes highlights the existence of trade-offs between maximizing total consumption, maximizing the consumption of the low-income classes and reducing income inequality.

Keywords: carbon tax, distributive impacts, general equilibrium analysis

La fiscalité sur le carbone est-elle forcément injuste ? Vrais défis et faux débats.

Résumé :

Cette recherche vise à dissiper les malentendus quant aux impacts redistributifs de la fiscalité sur le carbone, qui se sont avérés être un obstacle décisif à davantage de considération dans le débat public. Il s’agit d’éclairer l’écart entre les analyses d’équilibre partiel qui sont proches de la perception par les agents des coûts d’une taxation, et les analyses d’équilibre général qui restituent mieux ses conséquences ultimes. Il montre que l’impact réel sur l’inégalité de revenu des ménages n’est pas mécaniquement déterminé par les budgets énergétiques initiaux et leurs flexibilités, mais dépend aussi de la façon dont les recettes fiscales sont réinvesties et ses conséquences sur l’équilibre général. La comparaison de cinq situations de réinvestissement met en lumière l’existence de « trade-offs » entre la maximisation de la consommation totale, et la maximisation de la consommation des classes de bas revenu et la réduction de l’inégalité de revenu.

Introduction

Consistently prescribed as an efficient tool to mitigate climate change (since at least Pearce, 1991), the idea of a carbon tax periodically shows up on public agendas in industrialised countries, to be adopted in some instances (Finland, 1990; Sweden, 1991; Italy and Germany, 1999; Switzerland, 2008),¹ but to be rejected more often than not: failures of the French Mission Interministérielle sur l’Effet de Serre (1990), of the carbon-energy tax of the European Union (1992), of the BTU tax of the Clinton Administration (1993), of the ‘ecotax’ of the Jospin government in France again (1998), of the projects in Australia and New Zealand (Baranzini and al., 2000: 396), etc.

** CNRS, CIRED, 45 bis, avenue de la Belle Gabrielle, 94736 Nogent-sur-Marne CEDEX.
¹ The UK Road Fuel Duty Escalator (1993-1999) could be added to this list.
These failed attempts doubtlessly have specific historical reasons of their own. Still, they all seem to have faced a similar ‘refusal front’, based on two major arguments: that of competitiveness distortion, and that of a negative impact on the poorer households (Ekins, 1999). However well-grounded these fears, it is surprising to observe that they were systematically used to utterly reject the carbon tax, rather than treated as surmountable obstacles that merely required careful consideration in its implementation.

In the wake of the *Grenelle de l’Environnement*, a nationwide consultation held over the last quarter of 2007, the carbon tax came back on the French political agenda. However, the volatility of oil prices and the ongoing economic crisis currently strengthen the threat it seems to pose to the poorer households, which hinders its political acceptability. This article is consequently devoted to the equity argument, with as main objective to avoid that the actual stakes of a carbon tax reform be blurred by the misconception that the agent paying the tax is necessarily the one bearing its ultimate cost. The gap between the direct and the ultimate cost can indeed be substantial, as will be proven in the case of France.

**I. Perceived vs. real impacts**

**Reasons for the gap**

The immediate impact of a carbon tax on the welfare of households\(^2\) is obviously linked to the share of their budgets they devote to energy consumption. It is thus intuitively regressive (Parry *et al.*, 2005): the richer households admittedly consume more energy and are bound to pay more carbon tax in absolute terms, but the share of energy is larger in the budget of the lower-income households, at least in most OECD countries.\(^3\) The welfare of the lower-income households is thus *a priori* more impacted by both an income effect

\(^2\) The following analysis is restrained to the distribution of the economic cost of a carbon tax, *i.e.* does not extend to the distribution of the induced environmental benefits.

\(^3\) Although Bosquet (2000) points to exceptions, and Hassett *et al.* (2007) show that conclusions differ whether current consumption or current income are used as richness indicator. Pearson and Smith (1991) analyse 6 European countries to find that Ireland only shows a strong correlation between income and energy expenses. Scarce research on developing countries reveals a loose correlation, if not an inverse relationship (Yusuf and Resosudarmo, 2007).
(lower purchasing power of the disposable income), and the ‘necessity good’ quality of the carbon-intensive energy consumptions (stronger utility loss).

This basic reasoning already appears in early works by Poterba (1991) or Pearson and Smith (1991)—who also stress that the ‘partial equilibrium’ framework implicit behind it has substantial shortcomings: it assumes that energy producers or distributors pass the entire tax burden through to the consumers; it considers a fixed level and structure of energy supply and demand, thereby precluding adaptive behaviour; at last, it ignores the propagation of the carbon tax to other goods and services prices through their intermediate energy consumptions, and thus the ultimate effects on the economy and household income. This chain of effects resorts to fiscal incidence, which deals with possible discrepancies between the directly perceived distributive impacts and those ultimately resulting from ‘general equilibrium’ effects.

Partial equilibrium analyses were admittedly extended by allowing for consumption trade-offs through the introduction of price-elasticities differentiated by class. It turned out that such adaptive behaviour attenuates the immediate direct impact of a tax, but hardly ever reverses its sign. (Cornwell and Creedy, 1996; West and Williams, 2004). On the contrary, the use of input-output tables for evaluating the propagation of the tax effect to all prices tends to reinforce the regressive effect (Hamilton and Cameron, 1994; Hassett et al., 2007; Wier et al., 2005). But such computation, however close to the immediate perception of consumers and facilitated by quite simple arithmetic or linear algebra, ultimately reasons in a fictitious world: it assumes constant nominal income, and ignores the use made of the tax revenue, which disappears in some unexplainable potlatch.

Although less intuitive and consequently more contrasted, general equilibrium analyses are also more realistic in that they forbid any form of potlatch and guarantee a sort of ‘mass conservation principle’, through their representation of a balanced accounting framework. This indeed allows to demonstrate the crucial role of the recycling mode in determining the ultimate effect of a carbon tax. Historically general equilibrium analyses of the carbon tax were focussed on the ‘double dividend’ debate, i.e. the question whether the environmental benefit induced by a carbon tax could be combined to gains in economic growth and employment. While the abundant literature dedicated to this
question is still open to further research, it has nevertheless reached a rather consensual set of conclusions:

- Recycling carbon tax revenues in a decrease of a pre-existing distortive tax produces a ‘weak’ double-dividend, \textit{i.e.} achieves some environmental target at a lower welfare cost than other economic instruments as norms. The more distortive the pre-existing tax, the better. In Europe a consensus tends to view decreasing labour taxes (payroll taxes) superior to decreasing other taxes, subsidies, public deficit or debt reduction, \textit{etc.} (Hourcade \textit{et al.}, 2001).

- Obtaining a ‘strong’ double dividend, that is recycling the carbon tax proceeds in such a way that the total economic cost of the reform is negative, is far from being automatic. Intuitively, substituting a carbon tax to payroll taxes should indeed favour employment, and hence growth. But taxing carbon means taxing consumption, and taxing consumption is equivalent to taxing the income that pays for it. A payroll-tax substituting carbon tax thus ultimately ways on labour as a source of income, same as the levy it is replacing (Bovenberg and De Mooij, 1994a, 1994b; Goulder, 1994).

- The ‘strong’ double dividend potential is less elusive when accounting for the fact, as empirical models do, that the carbon tax burden is not entirely borne by labour or the national productive capital. Indeed it also weighs on non-wage household income (financial and property rents, transfer revenues), as well as on the oil and gas rent of exporting countries (Goulder, 1994; Ligthart, 1998). In total, the levy on national labour is indeed decreased and net gains can occur, all the more so as the labour market is rigid (Carraro and Soubeyran, 1996).

\begin{itemize}
\item \textsuperscript{4} Bovenberg (1999) provides a synthesis of the theoretical underpinnings. A survey of empirical studies can be found in the second, third and fourth Assessment Reports of the IPCC (Hourcade, 1996 and 2001; Barker, 2007).
\item \textsuperscript{5} Norms create rents benefitting the polluting industries beyond what is legitimated by the cost of their technological restructuring. Besides, the marginal cost of a norm is at least partially passed through to intermediate and final consumers, whereas that of a carbon tax can be compensated by a recycling in the decrease of other production taxes.
\item \textsuperscript{6} Besides, a carbon tax distorts the consumption goods market, thus degrading the utility households derive from their income. In stylized models like that of Bovenberg and De Mooij (op. cit.), where unemployment is voluntary, this discourages labour supply and depresses activity.
\end{itemize}
In this perspective, accounting for general equilibrium effects becomes crucial to assess the fate of low-income classes: a carbon tax that reduces income inequality can also reduce the latter classes’ welfare if it has a positive total cost; conversely, a carbon tax causing a strong double dividend, \textit{i.e.} inducing negative total costs, can increase income inequality while improving the welfare of the low-income class.

Notwithstanding, general equilibrium literature on the distributive effects of a carbon tax is much less abundant than that on the aggregate double dividend, and still less extensive than the partial equilibrium one on the same subject.\footnote{Let us still quote Proost and Van Regemorter (1995) on Belgium, and Yusuf & Resosudarmo (2007) on Indonesia.} As a matter of fact the passed decade has seen less research on the carbon tax because of the prejudice of a political impairment, despite the acknowledged theoretical potential\footnote{See the recent Harvard Project on International Climate Change Agreement (Aldy and Stavins, 2008). The body of the report stresses the advantages of coordinated national taxes; but these are barred from the summary because their adoption is seen as “politically unlikely”.}, and because of the attention gained by the tradable emission permit option, in the wake of the Kyoto Protocol.\footnote{This rests on a wrong interpretation of the Protocol, which indeed creates a permit market between States, but leaves to each State the choice of which domestic instruments to implement. A State could couple a fiscal reform with programs on buildings and transport, to become a permit seller on international markets without having created a domestic permit market.} The resulting weakness in the state-of-the-art requires the economist to be modest on the numerical results, but should not prevent him from delivering insights on the robust mechanisms determining the ultimate consequences of alternative carbon tax reforms.

The following two sections thus shed light on how the perceived impact of a carbon tax changes with the level of analysis. They envisage the implementation of a tax up to \(€200\) \textit{per} tonne of \(\text{CO}_2\) (hereafter \(\$/\text{tCO}_2\)) in 2004 France, whose household agent is divided into 20 income classes on the basis of an INSEE \textit{Budget des Familles} survey covering the years 2000-2001.\footnote{Following INSEE “income” is defined as total household income over household number of consumption units (CU), with CU measured following a modified OECD scale: 1 CU for the first adult, 0.5 CU for any other person above 14 and 0.3 CU \textit{per} children below 14.} The welfare index used to measure class impacts is the change in real consumption, \textit{i.e.} the sum of a class’s consumption expenses deflated by its specific Fisher price index. For the sake of clarity results are reported aggregated into 5
II. Lessons from partial equilibrium analysis

II.1. Direct impacts with constant energy consumptions

Let us first consider the impact of a carbon tax as spontaneously perceived at the time of its implementation, that is notwithstanding changes in the energy consumptions and their carbon intensities, in the relative prices net of the new tax, or in nominal incomes. Facing such constraints households can adjust their non-energy consumptions only. This provides a first order approximation of the tax effects.\footnote{The first order monetary measurement of the welfare variation (compensating variation) is the cost increase of the initial good and services consumed. This approximation is only valid for marginal price variations (Bourguignon and Spadaro, 2006).}

Unsurprisingly, from such an angle the carbon tax appears regressive whatever its level (Figure 1). Indeed, poorest, modest and median households alike consistently lose a share of their real consumption roughly one and a half times that lost by the richest households, for the simple reason that their energy budget share is respectively 38%, 36% and 33% higher—the higher rate of motorisation of the median and modest classes explains why their loss is closely comparable to that of the poorest class, despite lower budget shares.

household classes, of the 5% ‘poorest’, the 30% ‘modest’, the 30% ‘median’, the 30% ‘rich’ and the 5% ‘richest’ households.
Figure 1  Redistributive effects, partial equilibrium with constant energy consumptions

Figure 2  Redistributive effects, partial equilibrium with adaptive energy consumptions

Figure 3  Redistributive effects, partial equilibrium with adaptive energy consumptions and fixed per-CU recycling
II.2. Impacts after adaptation to the new relative prices

Turning to the ability of households to adapt to the new set of relative prices implies facing three difficulties related to estimating energy price elasticities:

- The questions raised by time series econometrics in energy matters: (i) the difference between short- and long-term elasticities, and the irreversibility or asymmetry effects of a price increase vs. a price decrease (Gately, 1992; Peltzman, 2000); (ii) the erratic nature of energy prices since the first oil shock in 1973, that make them ill-suited to provide estimates for stable policy-related price-signals; (iii) the questionable use of a general consumer price index to deflate current energy prices, considering the dominant role of a certain set of prices (e.g. that of house rental services) in the shaping of mobility demand.

- The lack of panel data over both a period long enough and sufficiently disaggregated households to grasp the long-term heterogeneity of households’ behaviour—acknowledging that the ability of households to adapt depends on, beyond their income level, parameters as diverse as the degree of urban sprawl, the share of rurality, or the equipment in infrastructures.

- The impossibility to reason with constant elasticities over the large spectrum of taxes tested in this paper, be it only because of the existence of basic needs and technical asymptotes to energy efficiency at any given temporal horizon.

For lack of a better solution, we derived own-price, cross-price and income elasticities that are, for each household class:

- Based on an Almost Ideal Demand System (Deaton and Muellbauer, 1980) estimated on long-term time series (INSEE, 2007);\(^{(12)}\)

- Decreasing with the tax level, in order to have consumption tend towards an asymptotic value meant as an incompressible basic need.\(^{(13)}\)

\(^{(12)}\) Elasticities for automotive fuel (-50% on average, standard deviation of 7%) and for residential energy (-11% on average, standard deviation of 12%) are comparable to values found in the existing literature (Graham and Glaister, 2002).

\(^{(13)}\) The reasons for this modelling choice are discussed in a special issue of The Energy Journal dedicated to hybrid modelling (Hourcade et al., 2006; Ghersi and Hourcade, 2006).
Energy asymptotic values are assumed identical for all classes and set at 80% of the lowest consumption per capita.

Taking account of these elasticities and asymptotes produces impact estimates that can be interpreted as those of a carbon tax having had sufficient time before 2004 to deploy its adaptation effects. These estimates seem very close to those obtained without adaptive behaviour (compare Figure 2 to Figure 1): for all household classes consumption flexibility only slightly alleviates the tax burden, and the regressive effect is hardly changed.\(^\text{14}\)

II.3. Introducing a ‘mass conservation’ principle

Before turning to the more complex general equilibrium effects, the partial equilibrium analysis can be further refined by the introduction of a simple ‘mass conservation’ principle, with the aim of correcting the ‘potlatch’ disappearance of carbon tax revenues. Let us assume that this revenue is redistributed to households as a fixed amount per consumption unit (CU). This recycling rule, through which a substantial share of carbon tax payments of the higher classes is redistributed to the poorer, results in a dramatically different distribution impact: whatever the tax level the reform turns out progressive (Figure 3).

That an obviously highly egalitarian recycling rule should lead to a progressive impact might appear tautological. This step is simply meant as a demonstration that, beyond the direct regressive effect of the carbon tax, the recycling mode of its fiscal product induces another distributive effect that is potentially strongly progressive.

In this context it is commonly recognised a good practice to analyse the ‘pure’ effect of taxation by simulating lump-sum recycling, i.e. that each agent or aggregate thereof gets its carbon tax payments refunded. Lump-sum recycling provides indeed a useful framework in which to compare the efficiency of diverse recycling options. But this does not mean that it is the only legitimate assumption to be made when assessing a double dividend potential, as is some-

\(^{14}\) Part of this lack of sensitivity is explained by the use of real consumption as indicator. Real consumption cannot capture ‘basket composition’ effects that would certainly show if some utility function could have been properly calibrated. Indeed, detailed modelling results reveal consumption decreases of up to 21% for automotive fuel, 5% for residential energy (for a €200/tCO\(_2\) tax).
times argued under the pretence that any other recycling option could be organised as an independent set of transfers between agents. It indeed remains that, if a carbon tax were levied, it would be desirable to explore the best possible recycling option. That best possible recycling option is as much part of the carbon tax reform as the tax itself.

Introducing a ‘mass conservation principle’ thus forces to jointly analyse the tax and its recycling, which is proven to loosen the mechanical link between the carbon tax and the regressive effect. Then general equilibrium modelling is required to grasp the simultaneous adaptation of agents to the diverse forms such general reorganisations of the fiscal structure can take.

III. Real distributive impacts: general equilibrium analyses

The analysis below is based on comparative static modelling conducted with the IMACLIM-S model. The version used is enhanced from previous ones\textsuperscript{15} by the disaggregation of 20 income classes, endowed with the adaptation capabilities described above, and by a detailed description of the national income distribution among the 20 classes, firms, public administrations and the rest of the world. The resulting financial positions are balanced by agent-specific interest rates on a financial market, and debt services duly represented.

Our purpose being to demonstrate the importance of the tax-recycling option, we choose to stick to a given macro-economic behaviour across all our simulations: identical decreasing relation between propensity to consume and income; fixed investment-disposable income ratio; identical technical asymptotes and basic needs; fixed nominal international prices; etc. Two sets of assumptions are crucial enough to deserve more exposition.

A first set regards public administrations. On the one hand, we assume a strict “euro for a euro” budget neutrality of the carbon tax: whatever its use the amount recycled is strictly identical to the amount levied, to the euro.\textsuperscript{16} On the

\textsuperscript{15} See Ghersi (2009) for a detailed description of the model; Ghersi and Hourcade (2006) for the particular stance regarding producer behaviour.

\textsuperscript{16} There are more than one interpretation of the budget neutrality hypothesis (constant fiscal pressure, constant absolute deficit, constant ratio of deficit to GDP, etc.), each of which have
other hand real public expenses are fixed (total consumption, total investment, per capita transfers) and the ratio of public debt to GDP as well. Eliminating the latter two adjustment variables facilitates the comparison of different options. It also triggers either a vicious or a virtuous circle, as it implies the need to raise or lower other taxes, depending on whether the variations of the fiscal bases compensate the direct losses of the interior tax on petroleum products (hereafter TIPP according to the French acronym) caused by the drop in automotive fuel consumption.\footnote{The VAT on automotive fuel does not constitute such losses as the VAT is similarly levied on any consumption that is substituted to them (if in some instances at a reduced rate).}

A second set of assumptions relates to the labour market and its degree of imperfection. First, to represent structural situations of unemployment and limited wage flexibility, we adopt a wage curve (Blanchflower and Oswald, 2005) that correlates the average wage relative to foreign prices to the unemployment rate. The choice of correlating the foreign-prices relative wage rather than the real wage (\textit{i.e.} relative to some domestic consumer price index) is made to reflect competitiveness constraints specific to the French-European Union context. It forces a wage moderation that sets limits on the energy price propagation effects and amplifies a trade-off in favour of labour, but simultaneously allows for higher real wage losses. Second, aggregate employment impacts are assumed to affect classes proportionally to their initial number of unemployed—which makes classes all the more sensitive to employment variations as they are poor. This simplifying assumption is adopted for lack of information and should be revised in future research.

The resulting modelling framework is applied to simulate 5 reforms (Table 1):

\begin{itemize}
\item The R1 reform consists in taxing carbon emissions from the households, then refunding them the entire tax product as a fixed amount per CU—a reform identical to the one assessed with the introduction of a ‘mass conservation’ principle above.
\item The R2 reform enlarges the carbon tax base of R1 to carbon emissions from the firms.
\end{itemize}
• The R3 reform covers emissions as R2 but recycles the tax proceeds in a decrease of payroll taxes.

• R3ND and R4 reforms, are two variants that impose a neutralisation of the distributive impacts.

III.1. Recycling modes and activity levels: towards an equity-efficiency dilemma?

By nature, shifting to a general equilibrium framework multiplies the criteria for comparing different policies. Focussing on the reforms R1 to R3 to begin with, we will start by delineating their aggregate economic impact, and then examine how this aggregate impact is distributed among household classes.

R1 has a decreasing effect on GDP (Table 2), fundamentally consistent with the theoretical analysis stressing that taxing one good is less efficient than putting the same burden on total income—because of the Slutsky substitution effect. In our simulation this effect is not compensated by the mild growth stemming from a redistribution in favour of the poorer classes and their higher propensity to consume, notably because our budget neutrality constraint implies increases of the pre-existing taxes. The net effect on employment is nonetheless mildly positive (+0.15% for a tax level of €200/tCO₂), thanks to a shift in demand towards labour-intensive rather than energy-intensive goods.

R2, by extending the tax base to emissions from firms, increases the GDP losses. This is again consistent with theoretical results (Bovenberg and Goul-
In the light of such GDP losses the consumption gains of R2 might seem paradoxical. They are permitted by a significant redistribution of national income in favour of households due to (i) the indexation of social transfers on prices; (ii) the payment to households of all carbon tax proceeds including those whose burden is ultimately borne by other agents. With fixed public expenses and debt levels financed through increased taxation, the cost of the reform
ends up particularly weighing on the real investment of firms, which decreases by 4.1% for a €200/tCO₂ tax. This decreased investment must result into lower technical progress, competitiveness and ultimately growth: the consumption gain of R2 can only be transitory.

The comparative results of R2 and R3 are themselves in line with the literature on second best economies (GIEC, 2000):¹⁸ using the carbon tax proceeds to lower payroll taxes increases the activity level. At €200/tCO₂ GDP increases by 1.5%, employment by 2.8%, and carbon emissions drop by 27%. On the latter environmental achievement it is interesting to note the hardly perceivable influence of the recycling mode; this indicates dominance of the direct impact of the tax on relative prices over any indirect effect, including the variations in activity.¹⁹

Let us now analyse how these impacts affect the different classes. Unsurprisingly R1, which strictly reproduces the ‘constant mass’ partial equilibrium variant (§ II.3), shows a comparable distributive impact (compare figures 3 and 4). However, general equilibrium mechanisms systematically decrease the welfare of the three richest classes, whereas they increase that of the poorest classes up to €120/tCO₂. The reason for this difference in sensitivity lies in heterogeneous income structures and labour market situations. The poorest and modest classes indeed have high proportions of their income (resp. 51% and 46%) guaranteed in real terms in the form of price-indexed social transfers. Besides, thanks to high unemployment rates (resp. 42% and 22%) they benefit relatively more from a mild labour creation effect (+0.15% for €120/tCO₂).

For the lower tax levels, these two benefits compensate the erosion of purchasing power caused by the increased fiscal pressure necessary to maintain public expenses and debt in a context of lower growth, which adds up to the direct energy price increase. By contrast the higher income classes face an income loss strongly correlated to the GDP decrease and that cannot be compensated by gains on the labour market that are limited by much lower unemployment levels.²⁰

¹⁸ Previous modelling analysis by IMACLIM has given comparable results (Hourcade and Gheresi, 2000; Gheresi et al., 2001).

¹⁹ For the obvious reason of a smaller tax base, R1 induces abatement that is up to half as high.

²⁰ This holds even though the gap between unemployment benefits and the average wage, i.e. the gain from employment creation, is strongly increasing with income.
Figure 4  General equilibrium distributive impact, reform R1

Figure 5  General equilibrium distributive impact, reform R2

Figure 6  General equilibrium distributive impact, reform R3
The distributive impact of R2 (Figure 5) is profiled as that of R1, but much more contrasted. This directly results from the multiplication by 2.5 of the tax proceeds, and their highly progressive recycling rule. The poorest households are strongly advantaged: at €200/tCO2 their yearly tax payments amount to €500, but the generalised per-CU recycling rule hands them back €2 131; the €1 631 balance amounts to 8% of their consumption expenditures. Then, the higher the income class, the smaller this balance compared to the revenue losses caused by macro-economic adjustments. It is still high enough to allow the median class to turn its R1 loss into a gain, but not so for the higher classes: at €916 for the highest class subject to a €200/tCO2 tax, it amounts to a modest 1.3% of consumption expenditures that cannot compensate a marked decline in activity income (wages and rents).

R3 results are quite different from those of R1 and R2: although R3 increases both the aggregate income and total household consumption (Table 2), it wid-
ens the gap between income classes. At €200/tCO₂ the real consumption increase of the richest class is ca. six times larger than that of the poorest (Figure 6). The lower income households are indeed compensated from the carbon tax burden through employment creation only, and lose the benefit of the direct redistribution scheme. Besides, the social transfers that guarantee them against GDP losses also limit their ability to benefit from GDP gains. By contrast the richer classes, less sensitive to higher energy prices, capture a greater share of the increased growth thanks to income sources that are more correlated to general activity.

In total, the comparison between R1, R2 and R3 ultimately leads to an equity-efficiency dilemma. R1 and R2, through the choice of a direct redistribution of the carbon tax proceeds to households, overturn the distributive impacts of the tax, but do so at the cost of GDP losses and, in the case of R2, of a decrease in investment that jeopardises future growth. Conversely, R3 improves both GDP and employment, but does so by renouncing to a direct action on income distribution, and consequently leads to an inequitable distribution of the fruits of this growth.

III.2. Options for a trade-off

The relative performance of R3 arguably encourages to derive variants of this reform that, while conserving its aggregate efficiency, might fare better in terms of equity. The spectrum of possible variants is quite large, and it is obviously beyond the scope of this paper to try to cover it. R₃ND and R₄ are merely selected to illustrate how the ultimate consequences of a carbon tax hang on the political compromises expressed in its recycling rule.

The R₃ND variant combines R₃ assumptions with a zero-sum transfer among household classes that aims at equalising their real consumption variations (Figure 7). Its aggregate impacts are very close to those of R₃ in both environmental and macro-economic terms (Table 2). Such a quasi separability of efficiency and equity indicates that the behaviour of income classes is not heterogeneous enough to substantially modify the carbon tax impact on the pro-

---

21 The mild macro-economic advantage of R₃ND over R₃ is caused by the higher propensity to consume of lower income classes, who benefit from the transfers at the expense of the richer classes.
ductive system, aggregate consumption and emissions. However, any optimis-
tic inference on a possible conciliation of both criteria must be qualified by a
caveat concerning political acceptability: $R_{3\text{ND}}$ submits the richer classes to a
double levy (levy to compensate the poorer households on top of the carbon
tax) that could only be justified under a general political compromise to de-
crease inequalities.

The $R_{4}$ variant, at last, anticipates any argument about the burden sharing be-
tween households and firms by opting for a scheme that redistributes their own
tax payments to the former, and uses the tax payments of the latter to decrease pay-rol taxes. The share of the proceeds redistributed to households then al-
lows to control the distributive effect in a manner similar to that of $R_{3\text{ND}}$ (Fig-
ure 8). The macroeconomic and distributive impacts of $R_{4}$ turn out to fall be-
tween those of $R_{2}$ on one side, and $R_{3}$ on the other side. By contrast to $R_{2}$
GDP increases, as production costs benefit from the recycling of the tax pro-
ceeds levied on intermediate consumption; this generates consumption gains
that, by contrast to $R_{3}$, are distributed in a controlled manner.

Conclusion

This paper demonstrates that, contrary to a misconception inherited from par-
tial equilibrium analyses, there is no mechanical link between a carbon tax and
its ultimate distribution effects. On the contrary, the implementation of a car-
bon tax invites to a political trade-off through the choice of a recycling rule. A
direct redistribution of the tax proceeds to households ($R_{1}$ and $R_{2}$ reforms)
can be used to favour the poorest classes, but at the cost of lower investment
and competitiveness that shed doubt on its sustainability. A recycling in lower
payroll taxes results in higher growth, and a higher consumption for the poor-
est classes ($R_{3}$ reform); besides, the corresponding reform can be amended to
avoid any increase in income inequality ($R_{4}$ variant).

---

22 This dual recycling has been prevailing in Switzerland since January 2008: tax proceeds levied
on intermediate consumption are redistributed to firms on the basis of their labour costs; those
levied on final consumption are redistributed to households through a rebate on their public
health insurance cost.
