Abstract: Sericin is a natural silk protein which is removed from silk in a process called degumming. Thus, finding a use for the extracted sericin as a biopolymer film will create added value product which will benefit both the economy and society. The films were manufactured with silk sericin, using different dimethylolurea (DMU) concentrations as cross-linking agent and glycerol as plasticizer. Sericin films produced by crosslinking method were light yellow, homogeneous, transparent and visually attractive. The average film thickness was 0.10 ± 0.02 mm. The biofilms show low water solubility (up to 30% of total dry mass), good tension strength and high elongation ability. The water vapor permeability is moderate, typical of highly hydrophilic films. Structural transformations in silk sericin films were analyzed using Fourier transform infrared-attenuated total reflection (FTIR-ATR) spectroscopy and X-ray diffraction. This resulted in aggregated β-sheet structure (peak at 1616 cm⁻¹ in the amide I absorption) by FTIR studies and increasing the DMU concentration in film decreased the peak intensity at 2θ = 20º. Sericin-based film properties are dependent on components used to form film, which can used to tailor the desired film flexibility and minimize permeability of films.

Keywords: sericin, biofilms, crosslinking, gelification.

Introduction

Sericin is a highly hydrophilic macromolecular protein comprising of 18 amino acids. Molecular weight of sericin protein ranges from 24 to 400 kDa with predominant amino acid group’s serine (40%), glycine (16%), glutamic acid, aspartic acid, threonine and tyrosine. Thus it consists of polar side chain made of hydroxyl, carboxyl and amino groups that enable easy cross-linking, copolymerization and blending with other polymers to form improved biodegradable materials [1]. Silk sericin (SS) is one of essential components of cocoon filament comprising granular and high molecular proteins with adhesive and gelatin-like characteristics. The silk fibers are composed of a fibrous core protein fibroin (hydrophobic in nature) with sericin surrounding it [2]. Silks have evolved to be some of nature’s most impressive composite materials. Silk fibers are not only one of the toughest polymers known, but they have a number of other characteristics that, although less well known, make them an interesting as well as an important object for research in
the general areas of biopolymers, protein folding, biomimetics and the coevolution of behavior, morphology and function [3].

While manufacturing silk, sericin is removed as waste during the degumming process. If sericin can be utilized to make biofilms as a value-added product developed from the wastes, it will represent a significant source of profit, not to mention the beneficial effect of waste reduction for pollution prevention. This study finds an interesting application.

Sericin with such high potential has been always neglected in the field of tissue engineering due to its weak structural properties and high water solubility. Chemical crosslinking has shown to be an effective approach to suppress excessive swelling of biofilms in order to retain a high selectivity, although this is often accompanied with a reduction in the permeation flux. Films crosslinking will also help improve the thermal, chemical and mechanical stabilities of the films. In the present study, chemically crosslinked sericin films were developed. Dimethylolurea (DMU) appears to be an appropriate crosslinking agent as the crosslinking will occur primarily through the hydroxyl functionality of the polymers [4].

The present work establishes a methodology to obtain sericin films with different characteristics. The effect of the crosslinking agent (DMU) concentration on the properties of sericin films was evaluated.

**Experimental**

Sericin was extracted from the cocoons of Bombyx mori silkworm. The cocoons were cut into small pieces (about 1 cm²) and then immersed in destilate water in ratio 3:100 (w/v). The first step, aqueous SS solutions were extracted with hot water under pressure at 120 ºC for 60 min using an autoclave. In the second step, the solution was then deep frozen at -20ºC to enhancing precipitation. The frozen solution was later defrosted and filtered under vacuum. The concentration of SS was adjusted to 2 wt % before use. DMU (HPLC grade, Sigma-Aldrich, USA) was used as crosslinking agent and glycerol (Synth, Brazil) as plasticizer.

*Preparation of sericin films*

Sericin films were made by casting. Polymer solution with mass fraction of sericin (2 % w/v) was prepared in distilled water already containing glycerol (0.6 g glycerol/g sericin) at room temperature. The solution was mechanically stirred for about 1 h to ensure homogeneity. Afterwards, the temperature of the system was raised to 70 ºC and a dilute aqueous DMU solution was added to the biopolymer solution until a total amount of 0.1, 0.2, 0.4, 0.6 and 0.8 g DMU/g sericin. A defined amount (70 g) of the crosslinked film forming solution was poured into
polystyrene Petri dishes (d = 15 cm) and dried in a convection oven (Marconi – MA035, Brazil) at 40 °C for 18 h. All films were conditioned at room temperature and 52% RH inside desiccators for 3 days before characterization.

**Film characteristics**

*Solubility in water, \( S_W \)*

The solubility in water of the films was measured as proposed by [5]. The moisture weight fraction, \( \omega \), of the film was gravimetrically determined in a vacuum oven (Lab-Line, Squaroid, USA) at 105 °C for 24 h. Disks cut from the same film (\( d = 2.5 \) cm), were weighed (total mass \( m_o \)) and immersed in 50 mL of distilled water using a 250 mL beaker maintained under mild agitation (175 rpm) at 25 °C for 24 h (Tecnal, TE-421). The final dry matter (\( m_f \)) of the sample was determined in the same vacuum oven (105 °C/24 h). The fractional solubilized matter (\( S_w \)) was calculated as a function of the initial dry matter using Eq. (1).

\[
S_W = \frac{m_o (1-\omega) - m_f}{m_o (1-\omega)}
\]  

(1)

**Mechanical properties**

Tensile strength (TS) and percentage tensile elongation at break (E) of the preconditioned films were determined at room temperature using a TA.XT2 (Stable Microsystems SMD, England) according to ASTM standard method D882 [6].

*Water vapor permeability coefficient (WVP)*

The water vapor permeability coefficient through the films was determined gravimetrically at 25 °C according to method E96-95 [7]. Granulated calcium chloride (0% RH) was used inside the cells as desiccant. The cells were placed inside desiccators maintained at a constant relative humidity of 75% obtained with saturated NaCl solution. The water vapor permeability coefficient (WVP) was then calculated using Eq. (2). All determinations were made in triplicates.

\[
WVP = \frac{[(G/t) \cdot L]/[A \cdot P_w \cdot (RH_1 - RH_2)]}{[(G/t) \cdot L]/[A \cdot P_w \cdot (RH_1 - RH_2)]}
\]  

(2)

where \( WVP \) is the water vapor permeability coefficient [g mm/(m² day kPa)]; \( L \) is the average thickness of the film [mm]; \( G/t \) is the apparent steady state rate of weight gain [g/day]; \( t \) is the total time [day]; \( A \) is the permeation area [m²]; \( (RH_1 - RH_2) \) is the difference of relative humidities [=0.75] and \( P_w \) is the partial water vapor pressure at test temperature (25 °C) [kPa].

**Fourier transformed infrared spectroscopy**

Infrared spectra were collected using a FTIR spectrometer Varian – series 7000 at a wave-number region of 600-2000 cm⁻¹, resolution of 2 cm⁻¹ and the scan frequency of 16 times.
**X-ray diffraction**

X-ray diffraction intensity curves were obtained at a scanning rate of 0.0015° s\(^{-1}\) for 2\(^{\circ}\) from 5 to 50\(^{\circ}\) with a diffractometer Shimadzu - D 6000 using Cu radiation.

**Statistical analysis**

Analysis of variance (ANOVA) and Tukey Test were used to determine statistically significant differences (p < .05) among averages using the Software Statistica 7.0.

**Results and discussion**

**Films physical characterization**

Sericin films produced by crosslinking method were light yellow, homogeneous, transparent and visually attractive, whereas glycerol extended film flexibility. The average film thickness was 0.10 ± 0.02 mm. The use of a limited amount of crosslinking agent was necessary to consolidation of the film structure and the addition of DMU reduced film flexibility.

The water solubility of the sericin films with different concentrations of DMU are shown in Table 1. The solubility in water of the films conditioned at 52% RH decreased consistently and significantly by increasing the DMU content present in the crosslinking solution. This is probably caused by the higher crosslinking degree obtained by the sericin films when a DMU determinated concentration was used and the better aligned incipient polymeric structure assisted the strengthening action to formation film. Zactiti and Kieckbusch [8] also observed a decrease in solubility after crosslinking with CaCl\(_2\) in sodium alginate films.

It was well established that an increase in DMU content decreased film WVP. The WVP of sericin films with more content of DMU was lower than that from low content of DMU sericin films as shown in Table 1. These results indicated that molecular environment of silk sericin was affected by the addition of DMU not conformation but packing of molecular chains.

A comparison between the experimental data (Table 1) confirms that variations in the DMU concentration exert an appreciable reducing effect on film elongation but only a moderate positive effect on film tensile strength. According to the classification established by Krochta and De Mulder-Johnston [9], the water vapor permeability and the mechanical attributes obtained by sericin films can be considered as moderate, compared to synthetic films.

Structures of sericin films

Structural transformations in sericin films were analyzed using X-ray diffraction and FTIR studies. The result of wide-angle X-ray diffraction curve intensity is shown in Fig. 1. Miyake [10] studying high molecular weight sericin films found a diffraction peak near $2\theta = 20^\circ$, and a shoulder peak at near $2\theta = 12^\circ$, $28^\circ$, and $43^\circ$. In the present study, on further crosslinking with DMU, sericin films showed a decrease in peak intensity at $2\theta = 20^\circ$. Earlier studies suggested native sericin containing both random coils and $\beta$-sheets representing amorphous and crystalline regions respectively [2] and upon crosslinking with DMU caused a transformation of $\beta$-sheet and aggregated $\beta$-sheet structure to random coil due to intermolecular hydrogen bonding [11]. This resulted in a decrease in the amount of crystallinity of X-ray diffraction curve. FTIR was used to confirm secondary structural transition, when crosslinking with DMU (Fig. 2).

Figure 1. Wide angle X-ray diffraction patterns of sericin films.
There are four different types of distinguishable vibration peaks associated with protein amide-amide I (1616 cm\(^{-1}\)), amide II (1530 cm\(^{-1}\)), amide III (1242 cm\(^{-1}\)) and amide IV (667 cm\(^{-1}\)). Amide bonds form the polypeptide backbone and due to specific vibrational frequencies result in conformational changes in protein molecules. Crosslinking with DMU caused changes in the secondary structure of sericin films (Fig. 2). The appearance of bands between 1610 and 1625 cm\(^{-1}\) is often observed for solvent and thermally denatured proteins. The stronger the hydrogen bond involving the amide C=O, the lower the electron density in the C=O group and the lower the amide I absorption appears. Hence, the absorptions at lower wavenumber (1616 cm\(^{-1}\)) are attributable to aggregated strands having strong intermolecular hydrogen bonds among extended chains [12].

**Conclusions**

Transparent and homogenous sericin films were obtained after a reticulated film manufactured by casting. The increase in DMU concentration in the film increases the tensile strength of sericin films and decreases the solubility in water, moisture content, water vapour permeability and their elongation at break, resulting in a decrease in the amount of crystallinity. As a compromise between film mechanical resistance and flexibility, keeping low solubility, the use of 0.4 g DMU / g sericin is recommended.
